Case Report

A curious case of concealed abdominal hematoma in a 34-week pregnant woman, masquerading as eclampsia and diabetic ketoacidosis: A case report of maternal near-miss

ABSTRACT

A 34-week pregnant woman with apparently normal antenatal visits, presented to the Emergency department with drowsiness, very high blood pressure, and episodes of seizure 3 hours back. She was provisionally diagnosed as eclampsia with diabetic ketoacidosis. She was intubated and resuscitated for the same. However, in the intensive care unit, a point-of-care ultrasound of the abdomen showed free fluid and blood clots in the abdominal cavity, suggesting uterine rupture. Emergency surgical intervention saved the life of the patient.

1. Introduction

Maternal mortality is one of the major indicators of health care and a lot of resources are invested by the government to reduce maternal mortality.1,2 Severe acute maternal morbidity (SAMM), also known as "near miss", is defined as "A very ill pregnant or recently delivered woman who would have died had it not been that luck and good care were on her side." 3 Point-of-care ultrasound (POCUS) has been found to be the greatest accessory widely used by intensivists managing critically ill patients, whereby they can accurately and rapidly assess for many pathologies at the bedside. Here, we present a case in which maternal life was saved by the POCUS.

2. Case Presentation

A 32-year-old obese G2P1L1mother attended a local hospital due to a decreased perception of fetal movements for one day. Ultrasound (USG) of the abdomen was done, which showed intrauterine fetal demise (IUD). While under observation, the patient had seizure-like activity, and her blood pressure was 140/100 mm of Hg, suspected antepartum eclampsia. She received an injection of Magnesium sulfate 10 gm intravenously and was referred to our tertiary care hospital for further management.

On presentation to our obstetrics emergency, she was irritable and irrelevant talking, her pulse rate was 120/min, feeble, SpO2 90% on room air, and her BP, which initially was 190/100, came down to 90/60 mm of Hg. Pallor was present without any other significant physical finding. On per abdominal examination, the uterus was 32 weeks in size; fetal heart rate (FHR) was not recordable (confirmed by hand-held Doppler). There was no bleeding per vaginum.
The patient was started with oxygen by face mask and rapid infusion of 1 liter of normal saline. Blood glucose was 400 mg/dl. Arterial blood gas showed severe metabolic acidosis, leading to suspicion of new-onset Diabetic ketoacidosis (DKA). In the course, the patient had one more episode of seizures. Injection of Lorazepam 4 mg IV was given, and the patient was shifted to the Intensive care unit (ICU) with oxygen support.

In the ICU, the patient’s vitals were GCS-E2V1M4, pulse rate 130/min, and blood pressure unrecordable, ABG showed pH 6.9, PaO₂ 178 mmHg, PaCO₂ 38 mmHg, HCO₃ 10, lactate 12. The patient was intubated with rapid sequence intubation using fentanyl and succinylcholine with the help of bougie, as the airway was difficult due to obesity and pregnancy-related changes. Adequate ventilation was assured.

Noradrenaline was initially started at a low 4 mcg/kg/hr through the peripheral line. Insulin infusion started given high blood glucose, and sodium bicarbonate infusion started because of severe metabolic acidosis causing hemodynamic instability.

The response to the initial vasopressor was not adequate. Hence, central venous access was done, and noradrenaline support was increased to a dose of 20 mcg/kg/hr along with Vasopressin 2.4 unit/hr and Adrenaline 10 mcg/kg/hr in an attempt to maintain the mean arterial pressure. With this, we searched for any possible cause of undifferentiated shock.

A point-of-care ultrasound of the abdomen was done, which showed the uterine cavity with a placenta and a huge retro placental hematoma (Figure 1), which did not take up color (Figure 2). The fetus was found outside the uterine cavity in the peritoneal cavity, surrounded by heterogenous lesions suggestive of blood clots (Figure 3).

In the meantime, a thorough history of the patient’s progress and evaluation of recent documents showed that Tab Misoprostol 200 mcg SL was administered to the patient, which is a very high dose for labor induction considering the later stage of pregnancy.

Due to suboptimal visualization by bedside ultrasound given obese maternal habitus, this finding was confirmed by a radiologist.

Consent was obtained from her husband, and with the maximal support of vasopressors, the patient was shifted to the operation theatre with information to the blood bank for the need for a massive transfusion.

In the operation theater, ASA standard monitors were attached and vitals were PR 130/min BP 90/40 with maximal vasopressor support. The patient was induced with, fentanyl 2mcg/kg, ketamine, and atracurium 0.5 mg/kg and maintained with O₂ and sevoflurane.

On laparotomy, a hemoperitoneum of 2,500 ml of fresh blood and 500 ml of clotted blood was suctioned out. The dead fetus was lying in the peritoneal cavity and was delivered by breech extraction. The Placenta was delivered in toto. The uterus showed scar rupture with the extension of rupture till the fundus of the uterus, pooling of blood was seen, and bilateral fallopian tubes and ovaries were normal. Obstetric total hysterectomy was performed as a life-saving measure.
Massive blood transfusion protocol was activated and 3 PRBC, 3 FFP, 3 RDP were given in the ratio of 1:1:1. 1 ampule calcium gluconate 10 ml 10% slow IV over 10 minutes was given to avoid hypocalcemia.

After completion of the surgery, the patient was shifted to ICU. The vasopressor support gradually reduced over the next 12 hours, ABG returned normal, and the patient was extubated next day. She was discharged on the fourteenth postoperative day in good condition.

3. Discussion

In this patient, initial blood pressure and blood glucose were very high in response to the ongoing stress of uterine rupture or dextrose infusion from the peripheral center, which led to suspicion of DKA as ABG also showed severe metabolic acidosis due to shock (acute massive blood loss). This severe acidosis and hypotension may lead to a seizure that was further confused with eclampsia, as she had very high BP.

There was no bleeding per vaginum in this case, probably due to the sealing effect of a big baby on the cervix. On examination, the uterine contour appeared well maintained. This was probably due to the masking effect of obese maternal habitus.

Pregnants with preeclampsia should have a history of high blood pressure. However, there is no such history in this case. Also, the husband revealed that she had received a tablet of Misoprostol 200mcg peroral instead of PV.

According to the Nguefack et al., misoprostol was responsible for 71% of uterine rupture. 4 Pregnant patients with severe shock not responding to resuscitation with intravenous fluids and vasopressor support should lead to suspicion of ongoing bleeding inside the abdomen.

POCUS, where imaging is undertaken at the bedside, clinic, or emergency department (ED) by the clinician overseeing treatment, is a rapid form of assessment to find the bleeding sources that are not obvious. Indications for POCUS in obstetrics and gynecology are many and include Acute pelvic pain in patients of reproductive age and bleeding in early pregnancy. Hemodynamically unstable patient, etc. 5,6 Timely performed POCUS saved the mother’s life in our case and avoided maternal near-miss. 7

4. Conclusion

Timely intervention with a quick diagnosis with a skilled multidisciplinary team involving an obstetrician, anaesthesiologist, radiologist, and intensivist will help in complete recovery from maternal near-miss events.

A bedside point-of-care ultrasound helps in arriving at the correct diagnosis, thereby saving maternal lives.
